daily. Despite his initial recovery the patient’s condition worsened and he died 12 days after admission.

Discussion

This case demonstrates that C. famata may act as a central nervous system pathogen in immune-compromised individuals.

A study conducted on mice previously treated with cortisone demonstrated the organism’s potential to invade the central nervous system under immune-compromising conditions. Of these infected animals, 50% were killed while this species proved non-pathogenic to normal mice with no gross pathology, microscopic lesions or positive tissue cultures at the end of the experiment.

Our patient demonstrated a chronic clinical picture, with CSF special investigations supporting the diagnosis of meningitis caused by a fungal pathogen, with increased CSF lymphocytes, elevated CSF-protein and positive fungal culture. This patient being a case in point, with delayed dosing, early commencement of therapy and an adequate treatment and ineffective oral dosing probably leading to his death. The role of HIV as an immunosuppressive condition and possible co-factor for C. famata infection of the central nervous system could not be further investigated due to the death of the patient. C. famata is an uncommon human pathogen with few documented infectious conditions. The case presented shows the organism to be a possible novel pathogen in the human central nervous system. Failure to identify and recognise C. famata as a pathogen, combined with delayed therapy, especially when occurring in immune-compromised patients, may lead to unnecessary fatalities.

We thank R Lindeque-Kolver for supplying the clinical information.

Exclusive breast-feeding — a pipe dream?

To the Editor: In South Africa there is scepticism about the feasibility of exclusive breast-feeding (EBF) — despite success stories from Mexico, Bangladesh and Belarus. We report on the steps taken to develop a breast-feeding counselling and support strategy, which supports EBF, in a rural subdistrict in KwaZulu-Natal, where mixed feeding was the norm. Prior research showed that traditional beliefs and concerns about milk sufficiency or infant satiety/health were the main reasons for mixed feeding.

Between May and September 2000 we recruited matriculated women, living in the subdistrict, as breast-feeding counsellors (BCs). They were trained using the WHO/UNICEF breast-feeding counselling training course, a 40-hour course with a strong counselling component. Knowledge before and after training was assessed using a tool developed by the study team. A field guide, containing information from the course and appropriate suggestions addressing traditional beliefs that hinder EBF, was developed as an aide-mémoire to facilitate quality, consistent breast-feeding counselling. All BCs were trained to use the field guide. BCs recruited pregnant or breast-feeding women at clinics, and visited them at home at least once a week. The involvement of influential family members during home visits was encouraged. During each home visit, using the listening and learning skills from the course, BCs asked how feeding was going, whether additional feeds or fluids were given to the infant and reasons for these, and about breast health. They observed a breast feed, and then counselled the mother (and often the family) using 'building
confidence and support’ skills. Trainee supervisors (ex-BCs) provided on site support to BCs. Weekly meetings (study paediatricians and BCs) facilitated further learning.

We found that despite having no previous training in health care, BCs acquired knowledge quickly: the mean pre-course score was 52% (range 36 - 76%), while post-course scores were 80% (range 68 - 96%) immediately after the course, and 80% (range 66% - 92%) 3 months after the course. The average score in an open book assessment based on the field guide was 85% (range 66 - 99%). Although BCs initially ‘intervened’ rather than ‘counselled’, regular practice resulted in their becoming powerful counsellors, acquiring counselling skills more quickly than health care workers. Preliminary data found that 2 months into the intervention EBF rates had risen from less than 10% at 16 weeks4 to 49% at 20 weeks. Our experience leads us to believe that six elements are needed for a successful breast-feeding counselling and support strategy (Table I). These elements need to be incorporated into child health interventions to ensure sustainability.
