This case was challenging because of the long duration, presence of constitutional symptoms, recent ingestion of traditional medicament, shifting dullness and dullness in the flanks on clinical examination, previous non-significant rectal biopsy, ascites revealed on ultrasound examination, and unhelpful laboratory investigations.

Refractive surgery, mainly laser in situ keratomileusis (LASIK), is widely used to correct refractive errors, mainly myopia. It consists of producing a corneal flap, ablating the underlying corneal stroma using laser energy, and repositioning the flap without suturing it to the underlying stroma.

A 58-year-old man presented with blurred vision, pain and photophobia after suffering a minor injury on his right eye from a tree branch. He had had LASIK procedures 13 years ago for both eyes. The eye was congested, there was corneal fluorescein staining, and the corneal flap was partially detached and scrolled up (Fig. 1).

Under local sub-conjunctival anaesthesia the flap was irrigated, cleaned, repositioned and sutured. Methylprednisolone and gentamicin were injected subconjunctivally, and the eye was closed for 24 hours. The following day the eye was quiet with a visual acuity of 6/9 and the subsequent course was uneventful.

After a LASIK procedure the flap adheres to the corneal stroma because of the action of the endothelial pump and because the epithelium grows over the flap’s margin. Scarring and fibrosis occur only at the flap’s margin. Early and late complications are mainly haloes, glare, star-burst and dry eye. A dreaded complication is corneal ectasia.

Traumatic dislocation has been reported after 10 days, 1 year and 3 years and 5 months. Our report is the first to indicate the possibility of weak adhesion of the flap after a much longer time, i.e. 13 years.
